

Saturation and Condensate Fraction Reduction of Cold Alpha Matter

Abstract

The ground state energy of ideal α -matter at $T = 0$ is analyzed within the framework of variational theory of Bose quantum liquids. Calculations are done for three local $\alpha - \alpha$ potentials with positive volume integrals and two-body correlation functions obtained from the Pandharipande-Bethe equation. The energy per particle of α matter is evaluated in the cluster expansion formalism up to four-body diagrams, and using the HNC/0 and HNC/4 approximation for a Bose liquid. At low densities the two methods predict similar EOS whereas at higher densities they are sensitively different, the HNC approximation providing saturation at lower density, below the saturation value of nuclear matter. Inclusion of higher order terms in the cluster expansion of the condensate fraction is leading to a stronger depletion of the alpha condensate with the density compared to the two-body approximation prediction.

Key words: Alpha matter, variational theory of nuclear matter; cluster expansion; Hypernetted Chain Approximation; Bose-Einstein condensation.

1. Introduction

Renewed interest in the properties of α matter is manifest in the literature especially in connection with α -particle Bose-Einstein condensation (BEC) in α -like nuclei (see [1] and references therein). Calculations reported in this reference are pointing to the existence of a Bose-Einstein condensate of

Email address: misicu@theory.nipne.ro (Ș. Mișicu)
URL: <http://www.theory.nipne.ro/misicu/> (Ș. Mișicu)

α -particles at low densities. It was also noted by these authors that with increasing density the condensate fraction is reduced such that at density corresponding to the saturation of nuclear matter (≈ 0.04 α particles per fm^3), the condensate fraction is reduced to roughly one half. The estimation of the condensate fraction was done in the lowest approximation, i.e. the radial distribution function (RDF) is approximated by the square of the two-body correlation function (CFN), and therefore it is less justified for higher densities. There is however an old estimation by Clark and Johnson [2] for three values around the saturation density of nuclear matter using the hypernetted chain approximation in the lowest order (HNC/0), i.e. taking into account only nodal diagrams in the infinite density expansion of the RDF. It provides a severe reduction of the condensate fraction ($\approx 15\%$) compared to the lowest-order cluster expansion at the same density. On the other hand calculations of the cold α matter equation of state (EOS) reported by the same authors within the HNC/0 approximation and using the soft core $\alpha - \alpha$ potential of Ali and Bodmer [3] are predicting the saturation point at a high density ($\rho_\alpha \approx 0.085$ α particles per fm^3). These benchmark calculations of the α matter EOS were very recently compared to results obtained in the frame of the scalar ϕ^6 effective field theory with negative quartic and positive sextic interactions, to simulate the attractive character at long distances and repulsive at short distances, and found to be in a very good agreement [4]. Though no estimations of the condensate fraction are provided for this high density saturation point, from the estimation made at lower densities, as quoted above, we expect a stronger depletion of the BEC. One is then confronted with the problem that at low densities the α matter condensate is far from equilibrium, whereas at the saturation point the condensate fraction is small.

It was advocated that beyond a critical density ($\rho_\alpha^* \approx 0.03$ nucleons per fm^3), due to the strong overlap of the wave-functions and the unavoidable action of the Pauli principle, a total extinction of the α structure should occur [5]. The phenomenological $\alpha - \alpha$ potentials used in the past are systematically predicting saturation of α matter at densities considerably larger than this critical densities. It would then be important to establish if the saturation of the α matter takes place below this critical density if one employs other types of potentials that incorporate more microscopic input.

The aim of this letter is to analyse the α matter EOS over a wide range of densities and try to find the optimal CFN which reflects the interplay between the strong short-range and the long-range correlations that ultimately would

lead to saturation. Gaining insight in the saturation properties of α matter could also shed light on the condensate fraction reduction issue.

In what follows the g.s. energy of an infinite system of neutral α -particles interacting via two-body forces is calculated within the variational theory of Bose liquids. As input to the energy calculation we use a prescriptions for the CFN obtained by extremizing the energy functional in the two-body cluster approximation. The g.s. energy is then calculated via the cluster expansion adding the three-body and four-body correlations and with the HNC method that is more reliable in the high density sector.

2. Two-Body Potential

The $\alpha - \alpha$ potential is necessarily nonlocal due to the short range repulsion between α particles coming from exclusion effects. Phenomenological potentials obtained by inversion suffer of some difficulties which have not been yet fully resolved, mainly due to the limited range of energies where phase shifts have been measured. We remind the reader that potentials obtained by inversion are unique if and only if the corresponding phase shifts are known for fixed angular momentum for all energies, up to infinity, as required by Marchenko theorem [6]. If there exist bound states, asymptotic normalization coefficients for these states are necessary. Further, $\alpha - \alpha$ potentials are required to reproduce at least qualitatively the known resonances in ^8Be . These difficulties lead to a lot of ambiguities in the proposed $\alpha - \alpha$ potentials. For the typical Ali-Bodmer potential the nonlocality translates into a strong dependence of angular momentum in order to reproduce the repulsive effect of the redundant states in the $L=0$ and $L=2$ partial waves. We shall use the S -state Ali-Bodmer potential as representative for the class of phenomenological potentials with a soft inner repulsive core and a weak long range attractive component. There is however a more stringent requirement to be imposed on $\alpha - \alpha$ potential for α matter calculations. In ref.[7] the Euler-Lagrange equation for a Bose system within the HNC approximation was analyzed in detail and shown that a spherically symmetric solution which do not lead to a collapse of the system requires a potential with positive volume integral.

The Ali-Bodmer potential the α matter actually fails to saturate. In fact a very shallow minimum in the EOS at a high density is predicted. Other schematic potentials (hard core) are trivially saturating at densities and energies close to the nuclear matter saturation point ($\rho_\alpha \approx 0.04 \text{ } \alpha/\text{fm}^3$,

and $E/N_\alpha \approx -11-16$ MeV). However as we noted above, at such high densities the α -condensate is almost completely depleted according to the variational approach. Somehow this dissapointing result is conflicting with what would one expect based on the manifestation of α clustering in light real nuclei. The clusterization of α particles on the surface of nuclei at densities around half the central nuclear density, as revealed by α -decay, α -transfer reactions or the putative dilute three-alphas condensate in the Hoyle state of ^{12}C are pointing to a higher stability of α matter at lower densities.

Since the potentials providing saturation at lower densities are highly schematic (infinite repulsive short-range interactions) we resort to a calculation of the bare $\alpha - \alpha$ interaction based on the double-folding method for two ions at energies around the barrier. As input we consider realistic densities of the α -particle and modern effective nucleon-nucleon interactions.

In the double-folding framework [8] the interaction between two alpha clusters is calculated as a convolution of a local two-body potential v_{nn} and the single particle densities of the two clusters

$$v_{\alpha\alpha}(\mathbf{r}) = \int d\mathbf{r}_1 d\mathbf{r}_2 \rho_\alpha(\mathbf{r}_1) \rho_\alpha(\mathbf{r}_2) v_{nn}(\rho, \mathbf{r} - \mathbf{r}_1 + \mathbf{r}_2) \quad (1)$$

The effective $n - n$ interaction v_{nn} is taken to depend on the density ρ of the nuclear matter where the two nucleons are embedded. It should also consist of a density independent finite-range part with preferably two ranges such that a potential similar to the Ali-Bodmer is obtained. We therefore choose the Gogny effective interaction. Out of the three main parametrizations of this interaction, only the D1 [9] and the most recent one D1N [10] are satisfying the requirement of positive volume integral of the $\alpha - \alpha$ potential. The D1S parametrization [11] leads to a potential with negative volume integral and is omitted. .

In what follows we include only the direct part in the double-folding potential (1). The knock-on nonlocal exchange component leads to a strongly attractive local component mainly due to the fact that the Perey-Saxon localization procedure is not reliable at the energies of interest considered in this paper.

We take a Gaussian nuclear matter distribution inside the α -particle

$$\rho_\alpha(r) = 4 \left(\frac{1}{\pi b^2} \right)^{3/2} e^{-r^2/b^2} \quad (2)$$

with an oscillator parameter b that corresponds to a root mean square (rms) 1.58 ± 0.004 fm resulting from a Glauber analysis of experimental interaction cross sections [12].

The direct effective $n - n$ force in the Gogny parametrization reads :

$$v_{nn}^d(\rho, \mathbf{r}_1 - \mathbf{r}_2) = \frac{1}{2} \sum_{i=1}^2 (4W_i + 2B_i - 2H_i - M_i) e^{-|\mathbf{r}_1 - \mathbf{r}_2|^2 / \mu_i^2} + \frac{3}{2} t_3 \left[\rho \left(\frac{1}{2} (\mathbf{r}_1 + \mathbf{r}_2) \right) \right]^\gamma \delta(\mathbf{r}_1 - \mathbf{r}_2) \quad (3)$$

Inserting the gaussian density distribution (2) in the double folding integral (1) and using the Campi-Sprung prescription [13] for the overlap density

$$\rho(1, 2) = \left(\rho_\alpha(\mathbf{r}_1 - \frac{1}{2}\mathbf{s}) \rho_\alpha(\mathbf{r}_2 + \frac{1}{2}\mathbf{s}) \right)^{\frac{1}{2}}, \quad (4)$$

where $\mathbf{s} = \mathbf{r}_1 + \mathbf{r} - \mathbf{r}_2$ is the $n - n$ separation in the heavy-ion coordinate system [8], we obtain the $\alpha - \alpha$ potential,

$$v_{\alpha\alpha}(r) = 4 \sum_{i=1}^2 (4W_i + 2B_i - 2H_i - M_i) \left(\frac{\mu_i^2}{\mu_i^2 + 2b^2} \right)^{3/2} e^{-r^2 / \mu_i^2 + 2b^2} + \frac{3}{2} t_3 \frac{4^{\gamma+2}}{(\gamma+2)^{3/2} (\sqrt{\pi}b)^{3(\gamma+1)}} e^{-\frac{\gamma+2}{4b^2} r^2} \quad (5)$$

which is assumed to be the same in all partial waves. In the left panel of Fig.1 we represent the three potentials on a magnified scale around the minimum. The two selected Gogny interactions display shallower pockets that are shifted to larger radii compared to the Ali-Bodmer potential. Before ending this section we remark that a fictitious ${}^8\text{Be}$ (Coulomb interaction is switched off) is slightly bounded by Ali-Bodmer ($J^\pi = 0^+$, $E = -1.63$ MeV), loosely bounded by Gogny-D1N ($J^\pi = 0^+$, $E = -0.16$ MeV) and not bounded by Gogny D1 interaction, in agreement with the patterns depicted in Fig. 1. Levinson's theorem applied to the $\alpha - \alpha$ system [14] which predicts $\delta_0(E = 0) = 3\pi$, where δ_0 is the scattering phase for the $L = 0$ channel, is reasonably well satisfied by all potentials.

3. Variational approach

Within the variational approach to the description of a uniform system of spinless Bose particles at zero temperature interacting via a two-body

Figure 1: Different $\alpha - \alpha$ potentials used in this paper. On the left panel we zoomed on the pocket region whereas on right the panel we display also the soft-core.

potential $v_{\alpha\alpha}(r_{ij})$, the expectation value of the energy

$$E[\psi] = \frac{\langle \psi | H | \psi \rangle}{\langle \psi | \psi \rangle} \quad (6)$$

can be calculated using the Bijl-Dingle-Jastrow (BDJ) trial wave function [15]

$$| \psi \rangle = \prod_{i < j} f(r_{ij}) \quad (7)$$

Above, $f(r)$ is a positive semidefinite function that is required to reflect exclusively the two-body correlations. Thus at short distances, where the potential is expected to be strongly repulsive, f is small, whereas at large distances ($r \rightarrow \infty$), when the two-particle "decorrelate", $f(r) \rightarrow 1$.

The Jackson-Feenberg energy $\mathcal{E}_{\text{JF}}$, measured relative to the rest energy of N_α , α -particles, is [16, 17]

$$\mathcal{E}_{\text{JF}} = \frac{1}{2}\rho \int d\mathbf{r} g(r) \left[v_{\alpha\alpha}(r) - \frac{\hbar^2}{2m_\alpha} \Delta \ln f(r) \right] \quad (8)$$

where $g(r)$ is the two-body radial distribution function (RDF). This form of the energy has the advantage for bosons that terms including the three-body radial distribution function does not occur.

The cluster expansion formalism heavily relies on the fact that $h = f^2 - 1$ is of short-range and consequently the integral $\omega = \int h(r) d\mathbf{r}$ is small compared to the volume Ω of the system ($\omega = -\frac{1}{\rho} = \frac{\Omega}{N_\alpha} \ll \Omega$) [18]. Then g can be evaluated by an expansion in powers of ρ [19]. Including up to four-body diagrams the expansion reads

$$\begin{aligned} g(\mathbf{r}_{12}) &= f^2(\mathbf{r}_{12}) \left\{ 1 + \rho \int d\mathbf{r}_3 h(\mathbf{r}_{13}) h(\mathbf{r}_{23}) \right. \\ &+ \frac{1}{2} \rho^2 \int d\mathbf{r}_3 \int d\mathbf{r}_4 [2h(\mathbf{r}_{13}) h(\mathbf{r}_{24}) h(\mathbf{r}_{34}) (1 + 2h(\mathbf{r}_{14})) \\ &+ h(\mathbf{r}_{13}) h(\mathbf{r}_{23}) h(\mathbf{r}_{14}) h(\mathbf{r}_{24}) (1 + h(\mathbf{r}_{34}))] + \mathcal{O}(\rho^4) \left. \right\} \end{aligned} \quad (9)$$

The last term in the above formula include ring, diagonal, open and elementary four-body diagrams.

Retaining only the first term in the cluster expansion of g , the lowest-order Jackson-Feenberg functional is obtained upon substitution in the expression (8) of $\mathcal{E}$

$$\mathcal{E}_2[f, \nabla f, \Delta f] = \frac{1}{2} \rho \int d\mathbf{r} \left\{ v_{\alpha\alpha}(r) f^2(r) + \frac{\hbar^2}{2m} [(\nabla f(r))^2 - f(r) \Delta f(r)] \right\} \quad (10)$$

A practical method to obtain f is provided by the Pandharipande-Bethe prescription [20]. It consists in varying the two-body energy functional with respect to the one-parameter family of functions f under the constraint of normalization $\rho \int [f^2 - 1] d\mathbf{r} = -1$. Thus, the variational problem is reduced to the eigenvalue problem

$$-\frac{\hbar^2}{m_\alpha} \left(\frac{d^2 f}{dr^2} + \frac{2}{r} \frac{df}{dr} \right) + (v_{\alpha\alpha} - \lambda) f = 0 \quad (11)$$

The CFN is subjected to natural boundary conditions that reflect the Schrödinger condition at the origin of a soft-core and the necessity to heal to unity at a given distance d

$$u(r) \equiv r f(r) \xrightarrow{r \rightarrow 0} 0, \quad f(r \geq d) = 1, \quad f'(d) = 0 \quad (12)$$

For each density we varried the parameter d untill the normalization condition was fullfiled. In this way we obtained a solution that is density dependent (since we take $d \sim \rho^{-1/3}$), and the overshoot (the peak exceeding the unity) increase with density as can be seen in Fig.2 for all three potentials.

Figure 2: Correlation function $f(r)$ resulting from solving eq.(11) for the two cases : a) dependent on density at three different densities and b) unique for all densities. Each figure contains these correlations functions for a given $\alpha - \alpha$ potential.

Another recipe that we applied was to relax the normalization constraint and match instead the potential at the right boundary with the eigenvalue $\lambda = v_{\alpha\alpha}(d)$. This constraint is fulfilled for a unique d regardless the value assigned to ρ . The interpretation assigned by Pandharipande to the Lagrange multiplier λ is that of a contribution to the average field coming from the excluded particles. The corresponding CFN is then density independent and it does not display any overshoot. In both cases we select the lowest eigenvalue, corresponding to zero nodes of the CFN.

Naturally the validity of the cluster expansion is limited to low densities if the truncation is performed after including the four-body correlations. A method that allows the determination of g and is more reliable for higher densities is provided by the HNC approximation, where the diagrams belonging to the nodal set $\mathcal{N}$ are summed up to infinity. Thus, the RDF in HNC/0 approximation is defined as [21]

$$g(r) = f^2(r)e^{N(r)} \quad (13)$$

The function $N(r)$ results from the iterative solution of a set of non-linear equations

$$X(r) = g(r) - N(r) - 1 \quad (14)$$

$$N(r) = \int d\mathbf{r}_1 d\mathbf{r}_2 X(r_1)(X(r_2) + N(r_2))\delta(\mathbf{r}_1 + \mathbf{r} - \mathbf{r}_2) \quad (15)$$

Within the HNC/0 approximation elementary diagrams are neglected. The first correction to this approximation is given by HNC/4 , where the label 4 indicate that only the four-body elementary diagram is taken into account [22]. As a consequence expression (13) is modified, such that this diagram is added to the infinite number of nodal diagrams :

$$g(r) = f(r)^2 e^{N(r) + \epsilon_4(r)} \quad (16)$$

where [23]

$$\epsilon_4(\mathbf{r}_{12}) = \frac{1}{2} \rho^2 \int d\mathbf{r}_3 d\mathbf{r}_4 G(\mathbf{r}_{13}) G(\mathbf{r}_{23}) G(\mathbf{r}_{14}) G(\mathbf{r}_{24}) G(\mathbf{r}_{34}) \quad (17)$$

and $G(r)$ is a short-hand notation for $g(r) - 1$. Thus, within HNC/4 approximation we obtain a fully selfconsistent solution of equations (14)-(17).

4. Ground-state energy of α matter

The cluster expansion of the g.s energy results from inserting the expansion in powers of densities of the RDF (eq.(9)). The two-body and three-body terms are already given in the literature [19]. The four-body terms can be easily worked out employing the folding technique. Explicit expressions of the four independent diagrams contributing to this term were derived in [8]. On the other hand the g.s. energy in the HNC/0 approximation is obtained by simply substituting into (8) the RDF obtained from the iterative solution of eqs.(13)-(15)

Fig.3 displays the energies for the three potentials Ali-Bodmer, Gogny D1 and D1N calculated within the cluster expansion method (solid curves) and with the HNC/0 method (circled crosses) for both CFN resulting from the Pandharipande-Bethe equation. Upon comparison with the $\alpha - \alpha$ potential we remark a similar pattern. It became obvious earlier that when we move from the most attractive potential (Ali-Bodmer) to the most repulsive one (D1), the "molecular" pocket is shifted towards larger distances and shallower minima. The saturation point of the α matter EOS is considerably displaced to lower densities and instead of the overbinding manifest for the Ali-Bodmer potential we find a low-binding for the Gogny-D1 case. Another important feature of the obtained EOS is that the HNC/0 calculations produce less bound α matter with an obvious preference to saturate at lower densities. Although the cluster expansion formalism predicts softer EOS in

Figure 3: Total energy calculated with the cluster expansion (CE) taking into account up to four-body correlations contributions (solid lines) and with the HNC/0 method (circles) for the " ρ -independent" CFN considered in this paper.

the case of the ρ -independent solution, the HNC/0 results are almost identical for the two different choices of the CFN, a fact that suggests that most likely both are close to the optimal solution. As noted in [24] for the Bose homework problem, the fact that different looking correlation functions may give extremely close energies, is a general feature of the variational method.

The cluster expansion and HNC methods are similar over a larger range for the Ali-Bodmer potential, i.e. up to $\rho \approx 0.0225 \alpha$ per fm^3 whereas for the Gogny-D1 potential the interval is limited to $\rho \leq 0.0125 \alpha$ per fm^3 .

Previously HNC/4 calculations have been reported for the ${}^4\text{He}$ quantum liquid [23, 25] but to our knowledge there is no similar calculation for the g.s. of α matter. In Fig.4 we compare the EOS predicted in the two HNC approximations using the Gogny potentials. Apparently the contribution of the ϵ_4 diagram results only in a small lowering of the saturation energy.

From the EOS derived within the HNC/0 formalism we extracted the corresponding incompressibilities as a function of density (see Fig.4). Although the EOS for the Gogny-D1 interaction has the largest curvature, since the

Figure 4: Comparison between the EOS predicted with HNC/0 and HNC/4 for D1 and D1N potentials for both CFN selections.

saturation takes place at a rather small density ($\rho_{\text{sat}} \approx 0.015 \alpha \text{ per fm}^3$), the incompressibility is also small, $K \approx 64 \text{ MeV}$. Instead the Gogny-D1N interaction which predicts a saturation point at approximately $\rho_{\text{sat}} \approx 0.0325 \alpha \text{ per fm}^3$ and binding energy -16.8 MeV , provided we add the -7.07 MeV binding energy per nucleon of the α particle, has a corresponding value of K close to the generally accepted range of standard nuclear matter values, i.e. $K \approx 265.4 \text{ MeV}$. We note that within the dynamical lattice model of α matter with a Brink-Boeker I effective interaction by Tohsaki, a volume energy of -16.76 MeV and incompressibility $K \approx 181 \text{ MeV}$ are predicted [26].

From the inspection of Fig.4 we conclude that the interval where α matter develops thermodynamical instability ($K < 0$) is ranging over dilute densities for the Gogny D1 and D1N potentials, whereas for the Ali-Bodmer interaction also large values of the densities are affected by instability.

In our opinion the domain of thermodynamical instability provides a further ground to discard the Ali-Bodmer potential since it predicts a highly unstable α matter at densities where α clusterization is believed to be important. The Gogny D1 potential has saturation properties very close to the symmetric nuclear matter as can be noticed on Fig.4. On the other hand

although the Gogny-D1 interaction predicts a much softer EOS and a low binding energy, it displays instead stability at densities not far from the Mott density [5]. We therefore expect a realistic α matter EOS to develop a saturation point approximately in the domain bounded by the saturation points of the D1 and D1N EOS.

Figure 5: Incompressibility of α matter within HNC/0 for the three interactions Ali-Bodmer, D1 and D1N. The full circles specifies the saturation points and the dashed region the accepted range of symmetric nuclear matter saturation values.

5. Reduction of the Condensate Fraction

Another quantity of interest for the α matter ground state is the fraction of particles n_C filling the zero momentum state (BEC). Using a diagrammatic expansion, Ristig and Clark showed that n_C can be represented by irreducible n -body cluster diagrams $\Delta Q^{(n)}$, with two external points and $n - 2$ internal field points [27] :

$$n_C = e^{\Delta Q^{(1)} + \Delta Q^{(2)} + \Delta Q^{(3)} + \dots} \quad (18)$$

For the first three terms closed forms are available. Introducing the notation $\zeta(r) = f(r) - 1$ and making use again of the compact representation of

integrals via the convolution operation, the corresponding expressions are

$$\Delta Q^{(1)} = \rho \int d\mathbf{r} \zeta^2(r) \quad (19)$$

$$\Delta Q^{(2)} = \rho^2 \int d\mathbf{r} \left\{ \zeta(\mathbf{r})(\zeta * G)(\mathbf{r}) - \frac{1}{2}h(\mathbf{r})(h * G)(\mathbf{r}) \right\} \quad (20)$$

$$\begin{aligned} \Delta Q^{(3)} = & \frac{1}{6}\rho^3 \int d\mathbf{r}_2 d\mathbf{r}_3 d\mathbf{r}_4 (2\zeta(\mathbf{r}_{12})\zeta(\mathbf{r}_{13})\zeta(\mathbf{r}_{14}) - h(\mathbf{r}_{12})h(\mathbf{r}_{13})h(\mathbf{r}_{14})) \\ & \times [g_3(\mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) - G(\mathbf{r}_{23}) - G(\mathbf{r}_{43}) - G(\mathbf{r}_{24}) - 1] \end{aligned} \quad (21)$$

The calculation of the third-order contribution is greatly simplified by the fact that at the HNC/0 level, the tree-particle radial distribution function is given by the Kirkwood superposition approximation

$$g_3(\mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4) = g(\mathbf{r}_{23})g(\mathbf{r}_{43})g(\mathbf{r}_{24}) \quad (22)$$

Note that the three-body RDF is large only when all three alphas are close to each other (within distances of order $\rho^{-1/3}$). Details on the calculation of this last term will be presented elsewhere.

The exponential reduction of the condensate fraction is represented in Fig. 5 for the case when the second-order and the second plus third-order terms are added to the lowest order contribution for the three potentials used in this work. We perform an exemplification using only the density-dependent CFN. In all cases the third-order diagram is only slightly reducing n_C whereas the contribution of $\Delta Q^{(2)}$ is important beyond a certain density that is approximately $0.01 \alpha/\text{fm}^3$. As expected, in the case of the Ali-Bodmer potential the depletion of the condensate state with increasing density is smaller than in the case of Gogny potentials. Thus, whereas in the Ali-Bodmer case at saturation densities of nuclear matter ($\approx 0.04 \alpha/\text{fm}^3$) the depletion is around 35%, for the repulsive Gogny-D1 potential only a tenth of alphas are left in the condensate. On the other hand the HNC calculations employing Gogny potentials are predicting saturation at densities $\rho \approx 0.015 \alpha \text{ per fm}^3$ (D1) and $\rho \approx 0.0325 \alpha \text{ per fm}^3$ (D1N). As can be inferred from Fig.5 the condensate at this density is still well populated, i.e. 55% (D1) and 30% (D1N).

Figure 6: Reduction of the condensate fraction due to the contribution of higher order terms in the cluster expansion of the function Q for the three potentials used in this work.

6. Conclusions and Outlook

The properties of cold α matter have been analyzed using the framework of the variational theory. Compared to previous studies, performed mainly by Clark and collaborators, we introduce two new $\alpha - \alpha$ potentials that are based on the realistic α -particle densities and effective Gogny $n - n$ interactions widely used in modern nuclear structure studies. Hypernetted chain calculations including the elementary 4-body diagram are providing slight corrections to the HNC/0 approximation. For the low-density regime the cluster expansion method is providing results similar to the HNC, which means that predictions of the α matter g.s. properties in this case can be safely and rapidly obtained taking into account at most four-body correlations.

To our knowledge for the first time in the literature a detailed investigation of the condensate fraction for α matter was performed. The reduction of condensate fraction is enhanced once we take into account higher-order contributions in the cluster expansion of Q . For the Ali-Bodmer case the reduction is tempered by the more attractive character of the potential.

We inferred that only the Gogny-D1 based potential is predicting a saturation of alpha matter close to the Mott density. Moreover at this density there is a significant condensate fraction. On the other hand the Gogny-D1N EOS displays saturation properties (density, energy and incompressibility) similar to the symmetric nuclear matter EOS. For this reason we are confident that a realistic saturation point of the α matter should be located approximately in the range between 0.015 - 0.0325 α per fm^3 .

As mentioned in the introductory section the main factor that triggered this work was the renewed interest in the literature regarding the properties

of the α -condensate. We showed that compared to the dilute approximation adopted in ref.[1], the inclusion of higher order terms in the cluster expansion, produce a steeper depletion of the condensate, which is even more accentuated for the repulsive Gogny potentials.

The present work was also motivated by modern theories of low-density nuclear matter composed of neutrons, protons and alpha particles near the neutrinosphere during supernovae core-collapse (see [28]). In this context it would of interest to extend the present calculations to the case of non-zero temperature and inhomogenous distribution of α matter.
